Estimating winter balance and its uncertainty from direct

measurements of snow depth and density on alpine glaciers

ABSTRACT. Accurately estimating winter surface mass balance on glaciers is central to assessing glacier health and predicting glacier runoff. However, measuring and modelling snow distribution is inherently difficult in mountainous terrain. Here we explore rigorous statistical methods of estimating winter balance and its uncertainty from multiscale measurements of snow depth and density. In May 2016 we collected over 9000 manual measurements of snow depth across three glaciers in the St. Elias Mountains, Yukon, Canada. Linear regression, combined with cross correlation and Bayesian model averaging, as well as ordinary kriging are used to interpolate pointscale values to glacier-wide estimates of winter balance. Elevation and a windredistribution parameter exhibit the highest correlations with winter balance, but the relationship varies considerably between glaciers. A Monte Carlo analysis reveals that the interpolation itself introduces more uncertainty than the assignment of snow density or the representation of grid-scale variability. For our study glaciers, the winter balance uncertainty from all assessed sources ranges from $0.03 \,\mathrm{m}\,\mathrm{w.e.}$ (8%) to $0.15 \,\mathrm{m}\,\mathrm{w.e.}$ (54%). Despite the challenges associated with estimating winter balance, our results are consistent with a regional-scale winter-balance gradient.

26 INTRODUCTION

Winter surface mass balance, or "winter balance", is the net accumulation and ablation of snow over the 27 winter season (Cogley and others, 2011), which constitutes glacier mass input. Winter balance $(B_{\rm w})$ is half 28 of the seasonally resolved mass balance, initializes summer ablation conditions and must be estimated to 29 simulate energy and mass exchange between the land and atmosphere (e.g. Hock, 2005; Réveillet and others, 30 2016). Effectively representing the spatial distribution of snow on glaciers is also central to monitoring surface 31 runoff and its downstream effects (e.g. Clark and others, 2011). 32 Winter balance is notoriously difficult to estimate (e.g. Dadić and others, 2010; Cogley and others, 2011). 33 Snow distribution in alpine regions is highly variable with short correlation length scales (e.g. Anderton and 34 others, 2004; Egli and others, 2011; Grünewald and others, 2010; Helbig and van Herwijnen, 2017; López-35 Moreno and others, 2011, 2013; Machguth and others, 2006; Marshall and others, 2006) and is influenced 36 by dynamic interactions between the atmosphere and complex topography, operating on multiple spatial 37 and temporal scales (e.g. Barry, 1992; Liston and Elder, 2006; Clark and others, 2011; Scipión and others, 38 2013). Simultaneously extensive, high resolution and accurate snow distribution measurements on glaciers 39 are therefore difficult to acquire (e.g. Cogley and others, 2011; McGrath and others, 2015) and obtaining 40 such measurements is further complicated by the inaccessibility of many glacierized regions during the winter. 41 Use of physically based models to estimate winter balance is computationally intensive and requires detailed 42 meteorological data to drive the models (Dadić and others, 2010). As a result, there is significant uncertainty 43 in estimates of winter balance, thus limiting the ability of models to represent current and projected glacier 44 conditions. 45 Studies that have focused on obtaining detailed estimates of $B_{\rm w}$ have used a wide range of observational 46 techniques, including direct measurement of snow depth and density (e.g. Cullen and others, 2017), lidar or 47 photogrammerty (e.g. Sold and others, 2013) and ground-penetrating radar (e.g. Machguth and others, 2006; 48 Gusmeroli and others, 2014; McGrath and others, 2015). Spatial coverage of direct measurements is generally 49 limited and often comprises an elevation transect along the glacier centreline (e.g. Kaser and others, 2003). 50 Measurements are typically interpolated using linear regression on only a few topographic parameters (e.g. MacDougall and Flowers, 2011), with elevation being the most common. Other established techniques include 52 hand contouring (e.g. Tangborn and others, 1975), kriging (e.g. Hock and Jensen, 1999) and attributing 53 measured winter balance values to elevation bands (e.g. Thibert and others, 2008). Physical snow models have been used to estimate spatial patterns of winter balance (e.g. Mott and others, 2008; Schuler and others, 55

2008; Dadić and others, 2010) but availability of the required meteorological data generally prohibits their 56 widespread application. Error analysis is rarely undertaken and few studies have thoroughly investigated 57 uncertainty in spatially distributed estimates of winter balance (c.f. Schuler and others, 2008). 58 More sophisticated snow-survey designs and statistical models of snow distribution are widely used in the 59 field of snow science. Surveys described in the snow science literature are generally spatially extensive and 60 61 designed to measure snow depth and density throughout a basin, ensuring that all terrain types are sampled. A wide array of measurement interpolation methods are used, including linear (e.g. López-Moreno and others, 2010) and non-linear regressions (e.g. Molotch and others, 2005) that include numerous terrain parameters, as 63 well as geospatial interpolation (e.g. Erxleben and others, 2002; Cullen and others, 2017) including various 64 forms of kriging. Different interpolation methods are also combined; for example, regression kriging (see Supplementary Material) adds kriged residuals to a field obtained with linear regression (e.g. Balk and Elder, 66 2000). Physical snow models such as SnowTran-3D (Liston and Sturm, 1998), Alpine3D (Lehning and others, 67 2006), and SnowDrift3D (Schneiderbauer and Prokop, 2011) are widely used, and errors in estimating snow distribution have been examined from theoretical (e.g. Trujillo and Lehning, 2015) and applied perspectives 69 (e.g. Turcan and Loijens, 1975; Woo and Marsh, 1978; Deems and Painter, 2006). 70 The goals of this study are to (1) critically examine methods of converting direct snow depth and density 71 measurements to distributed estimates of winter balance and (2) identify sources of uncertainty, evaluate 72 their magnitude and assess their combined contribution to uncertainty in glacier-wide winter balance. We 73

interest of making our results broadly applicable.

The St. Elias Mountains (Fig. 1a) rise sharply from the Pacific Ocean, creating a significant climatic gradient between coastal maritime conditions, generated by Aleutian–Gulf of Alaska low-pressure systems, and interior continental conditions, driven by the Yukon–Mackenzie high-pressure system (Taylor-Barge, 1969). The boundary between the two climatic zones is generally aligned with the divide between the Hubbard and Kaskawulsh Glaciers, approximately 130 km from the coast. Research on snow distribution and glacier mass balance in this area is limited. A series of research programs, including Project "Snow Cornice" and the Icefield Ranges Research Project, were operational in the 1950s and 60s (Wood, 1948; Danby and others, 2003) and in the last 30 years, there have been a few long-term studies on selected alpine glaciers (e.g. Clarke,

focus on commonly applied, low-complexity methods of measuring and estimating winter balance in the

with steep walls and have simple geometries. Based on a detailed study of Glacier 2 (Wilson and others, 2013) and related theoretical modelling (Wilson and Flowers, 2013) we suspect all of the study glaciers to be polythermal.

96 METHODS

Estimating glacier-wide winter balance $(B_{\rm w})$ involves transforming measurements of snow depth and density into values of winter balance distributed across a defined grid $(b_{\rm w})$. We do this in four steps. (1) Obtain direct measurements of snow depth and density in the field. (2) Assign density values to all depth-measurement locations to calculate point-scale values of $b_{\rm w}$ at each location. Winter balance, measured in units of metres water equivalent (m w.e.), can be estimated as the product of snow depth and depth-averaged density. (3) Average all point-scale values of $b_{\rm w}$ within each gridcell of a digital elevation model (DEM) to obtain the gridcell-averaged $b_{\rm w}$. (4) Interpolate and extrapolate these gridcell-averaged $b_{\rm w}$ values to obtain estimates of

Table 2. Details of the May 2016 winter-balance survey, including number of snow-depth measurement locations along transects $(n_{\rm T})$, total length of transects $(d_{\rm T})$, number of combined snow pit and Federal Sampler density measurement locations (n_{ρ}) , number of zigzag surveys $(n_{\rm zz})$, number (as percent of total number of gridcells, and of the number of gridcells in the ablation area) of gridcells sampled $(n_{\rm S})$ and the elevation range (as percent of total elevations range and of ablation-area elevation range).

	Date	n_{T}	d_{T} (km)	$n_{ ho}$	$n_{\mathbf{z}\mathbf{z}}$	$n_{ m S}$	Elevation range (ma.s.l.)

						(8%, 14%)	(32%,47%)
Glacier 13	12–15 May 2016	941	18.1	19	4	468	2054 – 2574
						(6%, 14%)	(45%,62%)

 $b_{\rm w}$ in each gridcell across the domain. $B_{\rm w}$ is then calculated by taking the average of all gridcell-averaged $b_{\rm w}$ values for each glacier. For brevity, we refer to these four steps as (1) field measurements, (2) density assignment, (3) gridcell-averaged $b_{\rm w}$ and (4) distributed $b_{\rm w}$. Detailed methodology for each step is outlined below. We use the SPIRIT SPOT-5 DEM (40×40 m) from 2005 (Korona and others, 2009) throughout this study.

Field measurements

109

Our sampling campaign involved four people and occurred between 5–15 May 2016, which falls within the 110 period of historical peak snow accumulation in southwestern Yukon (Yukon Snow Survey Bulletin and Water 111 Supply Forecast, May 1, 2016). Snow depth is generally accepted to be more variable than density (Elder 112 and others, 1991; Clark and others, 2011; López-Moreno and others, 2013) so we chose a sampling design 113 that resulted in a high ratio (\sim 55:1) of snow depth to density measurements. In total, we collected more 114 than 9000 snow-depth measurements and more than 100 density measurements throughout the study area 115 (Table 1). 116 During the field campaign there were two small accumulation events. The first, on 6 May 2016, also involved 117 high winds so accumulation could not be determined. The second, on 10 May 2016, resulted in 0.01 m w.e 118 accumulation measured at one location on Glacier 2. Assuming both accumulation events contributed a 119 uniform $0.01 \,\mathrm{m}$ w.e accumulation to all study glaciers then our survey did not capture $\sim 3\%$ and $\sim 2\%$ of 120 estimated $B_{\rm w}$ on Glaciers 4 and 2, respectively. We therefore assume that these accumulation events were 121 negligible and apply no correction. Positive temperatures and clear skies occurred between 11–16 May 2016, 122 which we suspect resulted in melt occurring on Glacier 13. The snow in the lower part of the ablation area 123

127 Sampling design

124

125

126

The snow surveys were designed to capture variability in snow depth at regional, basin, gridcell and point scales (Clark and others, 2011). To capture variability at the regional scale we chose three glaciers along a transect aligned with the dominant precipitation gradient (Fig. 1b) (Taylor-Barge, 1969). To account for basin-scale variability, snow depth was measured along linear and curvilinear transects on each glacier (Fig. 1c) with a sample spacing of 10–60 m (Fig. 1d). Sample spacing was constrained by protocols for safe glacier travel, while survey scope was constrained by the need to complete all surveys within the period of peak

of Glacier 13 was isothermal and showed clear signs of melt and metamorphosis. The total amount of melt

during the study period was estimated using a degree-day factor for melting snow (Braithwaite, 2008) and

found to be small (<0.05 m w.e., see Supplementary Material) so no corrections were made.

accumulation. We selected centreline and transverse transects as the most commonly used survey designs in winter balance studies (e.g. Kaser and others, 2003; Machguth and others, 2006) as well as an hourglass pattern with an inscribed circle, which allows for sampling in multiple directions and easy travel (personal communication from C. Parr, 2016). To capture variability at the grid scale, we densely sampled up to four gridcells on each glacier using a linear-random sampling design (Shea and Jamieson, 2010) we term a 'zigzag'. To capture point-scale variability, each observer made 3–4 depth measurements within ~1 m (Fig. 1f) at each transect measurement location.

141 Snow depth: transects

While roped-up for glacier travel with fixed distances between observers, the lead observer used a single-142 frequency GPS unit (Garmin GPSMAP 64s) to navigate between predefined transect measurement locations 143 (Fig. 1e). The remaining three observers used 3.2 m graduated aluminum avalanche probes to make snow-144 depth measurements (Kinar and Pomeroy, 2015). The locations of each set of depth measurements, made by 145 the second, third and fourth observers, are estimated using the recorded location of the first observer, the 146 approximate distance between observers and the direction of travel. The 3-4 point-scale depth measurements 147 are averaged to obtain a single depth measurement at each transect measurement location. When considering 148 snow variability at the point scale as a source of uncertainty in snow depth measurements, we find that the 149 mean standard deviation of point-scale snow depth measurements is found to be <7% of the mean snow 150 depth for all study glaciers. 151

Snow-depth sampling was concentrated in the ablation area to ensure that only snow from the current accumulation season was measured. The boundary between snow and firn in the accumulation area can be difficult to detect and often misinterpreted, especially when using an avalanche probe (Grünewald and others, 2010; Sold and others, 2013). We intended to use a firn corer to measure winter balance in the accumulation area, but cold snow combined with positive air temperatures led to cores being unrecoverable. Successful snow depth measurements within the accumulation area were made either in snow pits or using a Federal Sampler (described below) to unambiguously identify the snow-firn transition.

159 Snow depth: zigzags

We measured depth at random intervals of 0.3–3.0 m along two 'Z'-shaped patterns (Shea and Jamieson, 2010), resulting in 135–191 measurements per zigzag, within three to four 40×40 m gridcells (Fig. 1g) per glacier. Random intervals were machine-generated from a uniform distribution in sufficient numbers that each survey was unique. Zigzag locations were randomly chosen within the upper, middle and lower regions

of the ablation area of each glacier. Extra time in the field allowed us to measure a fourth zigzag on Glacier

13 in the central ablation area at ~2200 m a.s.l.

166 Snow density

Snow density was measured using a Snowmetrics wedge cutter in three snow pits on each glacier. Within 167 the snow pits (SP), we measured a vertical density profile (in 10 cm increments) with the $5 \times 5 \times 10$ cm 168 wedge-shaped cutter (250 cm³) and a Presola 1000 g spring scale (e.g. Gray and Male, 1981; Fierz and others, 169 170 2009; Kinar and Pomeroy, 2015). Wedge-cutter error is approximately $\pm 6\%$ (e.g. Proksch and others, 2016; Carroll, 1977). Uncertainty in estimating density from SP measurements also stems from incorrect assignment 171 of density to layers that cannot be sampled (e.g. ice lenses and hard layers). We attempt to quantify this 172 uncertainty by varying estimated ice-layer thickness by ± 1 cm (<100%) of the recorded thickness, ice layer 173 density between 700 and $900 \,\mathrm{kg} \,\mathrm{m}^{-3}$ and the density of layers identified as being too hard to sample (but not 174 ice) between 600 and 700 kg m⁻³. When considering all three sources of uncertainty, the range of integrated 175 density values is always less than 15% of the reference density. Depth-averaged densities for shallow pits 176 $(<50\,\mathrm{cm})$ that contain ice lenses are particularly sensitive to changes in prescribed density and ice-lens 177 thickness. 178 While SP provide the most accurate measure of snow density, digging and sampling a SP is time and 179 labour intensive. Therefore, a Geo Scientific Ltd. metric Federal Sampler (FS) (Clyde, 1932) with a 3.2– 180 3.8 cm diameter sampling tube, which directly measures depth-integrated snow-water equivalent, was used to 181 augment the SP measurements. A minimum of three FS measurements were taken at each of 7–19 locations 182 on each glacier and an additional eight FS measurements were co-located with two SP profiles for each 183 glacier. Measurements for which the snow core length inside the sampling tube was less than 90% of the 184 snow depth were discarded. Densities at each measurement location (eight at each SP, three elsewhere) were 185 then averaged, with the standard deviation taken to represent the uncertainty. The mean standard deviation 186 of FS-derived density was $\leq 4\%$ of the mean density for all glaciers. 187

Density assignment

188

Measured snow density must be interpolated or extrapolated to estimate point-scale $b_{\rm w}$ at each snow-depth sampling location. We employ four commonly used methods to interpolate and extrapolate density (Table 3): (1) calculate mean density over an entire mountain range (e.g. Cullen and others, 2017), (2) calculate mean density for each glacier (e.g. Elder and others, 1991; McGrath and others, 2015), (3) linear regression of density on elevation for each glacier (e.g. Elder and others, 1998; Molotch and others, 2005) and (4) calculate

Table 3. Eight methods used to estimate snow density at unmeasured locations. Total number of resulting density values given in parentheses, with n_T the total number of snow-depth measurement locations along transects (Table 1).

Method	Source of	measured	Density assignment		
code	snow o	lensity	$_{ m method}$

S4			Inverse distance weighted		
F4			mean for a glacier (n_T)		

mean density using inverse-distance weighting (e.g. Molotch and others, 2005) for each glacier. Densities derived from SP and FS measurements are treated separately, for reasons explained below, resulting in eight possible methods of assigning density.

197 Gridcell-averaged winter balance

We average one to six (mean of 2.1 measurements) point-scale values of $b_{\rm w}$ within each DEM gridcell to 198 obtain the gricell-averaged $b_{\rm w}$. The locations of individual measurements have uncertainty due to the error in 199 the horizontal position given by the GPS unit and the estimation of observer location based on the recorded 200 GPS positions of the navigator. This location uncertainty could result in the incorrect assignment of a 201 point-scale $b_{\rm w}$ measurement to a particular gridcell. However, this source of error is not further investigated 202 because we assume that the uncertainty resulting from incorrect locations of point-scale $b_{\rm w}$ values is captured 203 204 in the uncertainty derived from zigzag measurements, as described below. Error due to having multiple observers is also evaluated by conducting an analysis of variance (ANOVA) of snow-depth measurement 205 along a transect and testing for differences between observers. We find no significant differences between 206 snow-depth measurements made by observers along any transect (p>0.05), with the exception of the first 207 transect on Glacier 4 (51 measurements), where snow depth values collected by one observer were, on average, 208 greater than the snow depth measurements taken by the other two observers (p<0.01). Since this was the 209

first transect completed and the only one to show differences by observer, this difference can be considered an anomaly. We therefore assume that observer bias does not affect the results of this study and no corrections to the data based on observer are applied.

213 Distributed winter balance

Gridcell-averaged values of $b_{\rm w}$ are interpolated and extrapolated across each glacier using linear regression (LR) and ordinary kriging (OK). The LR relates gridcell-averaged $b_{\rm w}$ to various topographic parameters and we use this method because it is simple and has precedent for success (e.g. McGrath and others, 2015). Instead of a basic LR however, we use cross-validation to prevent data overfitting as well as model averaging to allow for all combinations of the chosen topographic parameters. We compare the LR approach with OK, a data-driven interpolation method free of any physical interpretation (e.g. Hock and Jensen, 1999).

Linear regression 220 In the LR, we use commonly applied topographic parameters as in McGrath and others (2015), including 221 elevation, slope, aspect, curvature, "northness" and a wind-redistribution parameter (Sx from Winstral 222 and others (2002)); we add distance-from-centreline as an additional parameter. Topographic parameters 223 are standardized for use in the LR. For details on data and methods used to estimate the topographic 224 parameters see the Supplementary Material and Pulwicki (2017). Our sampling design ensured that the 225 ranges of topographic parameters associated with our measurement locations represent more than 70% of 226 the total area of each glacier (except elevation on Glacier 2, where our measurements captured only 50%). 227 The goal of the LR is to obtain a set of fitted regression coefficients (β_i) that correspond to each topographic 228 parameter and to a model intercept. The LR implemented in this study is an extension of a basic multiple 229 linear regression; we use cross-validation to avoid overfitting the data and model averaging to incorporate 230 every possible combination of topographic parameters. 231 First, cross-validation is used to obtain a set of β_i that have the greatest predictive ability (Kohavi and 232 others, 1995). We randomly select 1000 subsets of the data (2/3 of the values) and fit a basic multiple linear 233 regression (implemented in MATLAB) to the data subsets, thus obtaining 1000 sets of β_i . The basic multiple 234 linear regression calculates a set of β_i by minimizing the sum of squares of the vertical deviations of each 235 datum from the regression line (Davis and Sampson, 1986). Distributed $b_{\rm w}$ is then calculated using each 236 set of β_i by weighting topographic parameters by their corresponding β_i values for all DEM gridcells. We 237 then use the remaining data (1/3) of the values to calculate a root mean squared error (RMSE) between the 238

estimated $b_{\rm w}$ and the observed $b_{\rm w}$ for corresponding locations. From the 1000 sets of β_i values, we select the set that results in the lowest RMSE.

Second, we use model averaging to account for uncertainty when selecting predictors and to maximize the 241 model's predictive ability (Madigan and Raftery, 1994). Models are generated by calculating a set of β_i (as 242 described above) for all possible combinations of topographic parameters, resulting in 2^7 models (i.e. 2^7 sets 243 of β_i with the greatest predictive ability for each linear combination of topographic parameters). Using a 244 Bayesian framework, model averaging involves weighting all models by their posterior model probabilities 245 (Raftery and others, 1997). We weight the models according to their relative predictive success, as assessed 246 by the value of the Bayesian Information Criterion (BIC) (Burnham and Anderson, 2004). BIC penalizes 247 more complex models, which further reduces the risk of overfitting. The final set of β_i is then the weighted 248 sum of β_i from all models. Distributed $b_{\rm w}$ is obtained by applying the final set of β_i to the topographic 249 parameters associated with each gridcell. 250

Ordinary kriging

251

Kriging is a data-driven method of estimating variables at unsampled locations by using the isotropic spatial 252 correlation (covariance) of measured values to find a set of optimal weights (Davis and Sampson, 1986; Li 253 and Heap, 2008). Kriging assumes spatial correlation between sampling locations that are distributed across 254 a surface and then applies the correlation to interpolate between these locations. Many forms of kriging have 255 been developed to accommodate different data types (e.g. Li and Heap, 2008, and sources within). Ordinary 256 kriging (OK) is the most basic form of kriging where the mean of the estimated field is unknown. Unlike LR, 257 OK is not useful for generating hypotheses to explain the physical controls on snow distribution, nor can it 258 be used to estimate winter balance on unmeasured glaciers. However, we chose to use OK because it does 259 not require external inputs and is therefore an interpretation-free method of obtaining $B_{\rm w}$. 260

We used the DiceKriging R package (Roustant and others, 2012) to calculate the maximum likelihood covariance matrix, as well as the range distance (θ) and nugget for gridcell-averaged values of winter balance. The range distance is a measure of data correlation length and the nugget is the residual that encompasses sampling-error variance as well as the spatial variance at distances less than the minimum sample spacing (Li and Heap, 2008). A Matére covariance function with ν =5/2 is used to define a stationary and isotropic covariance and covariance kernels are parameterized as in Rasmussen and Williams (2006).

267 Uncertainty analysis using a Monte Carlo approach

Three sources of uncertainty are considered separately: the uncertainty due to (1) grid-scale variability of 268 $b_{\rm w}$ ($\sigma_{\rm GS}$), (2) the assignment of snow density (σ_{ρ}) and (3) interpolating and extrapolating gridcell-averaged 269 values of $b_{\rm w}$ ($\sigma_{\rm INT}$). To quantify the uncertainty of grid-scale and interpolation uncertainty on estimates of 270 $B_{\rm w}$ we conduct a Monte Carlo analysis, which uses repeated random sampling of input variables to calculate 271 a distribution of output variables (Metropolis and Ulam, 1949). We repeat the random sampling process 272 1000 times, resulting in a distribution of values of the $B_{\rm w}$ based on uncertainties associated with the four 273 steps outlined above. Individual sources of uncertainty are propagated through the conversion of snow depth 274 and density measurements to $B_{\rm w}$. Finally, the combined effect of all three sources of uncertainty on the $B_{\rm w}$ 275 is quantified. We use the standard deviation of the distribution of $B_{\rm w}$ as a useful metric of $B_{\rm w}$ uncertainty. 276 Density assignment uncertainty is calculated as the standard deviation of the eight resulting values of $B_{\rm w}$. 277 We calculate a relative uncertainty, as the normalized sum of differences between every pair of one hundred 278 distributed $b_{\rm w}$ estimates including $\sigma_{\rm GS}$ and $\sigma_{\rm INT}$, to investigate the spatial patterns in $b_{\rm w}$ uncertainty. 279

280 Grid-scale uncertainty (σ_{GS})

We make use of the zigzag surveys to quantify the true variability of $b_{\rm w}$ at the grid scale. Our limited data 281 do not permit a spatially-resolved assessment of grid-scale uncertainty, so we characterize this uncertainty 282 as uniform across each glacier and represent it by a normal distribution. The distribution is centred at zero 283 and has a standard deviation equal to the mean standard deviation of all zigzag measurements for each 284 glacier. For each iteration of the Monte Carlo, $b_{\rm w}$ values are randomly chosen from the distribution and 285 added to the values of gridcell-averaged $b_{\rm w}$. These perturbed gridcell-averaged values of $b_{\rm w}$ are then used 286 in the interpolation. We represent uncertainty in $B_{\rm w}$ due to grid-scale uncertainty ($\sigma_{\rm GS}$) as the standard 287 288 deviation of the resulting distribution of $B_{\rm w}$ estimates.

Density assignment uncertainty (σ_{ρ})

We incorporate uncertainty due to the method of density assignment by carrying forward all eight density interpolation methods (Table 3) when estimating $B_{\rm w}$. By choosing to retain even the least plausible options, as well as the questionable FS data, this approach results in a generous assessment of uncertainty. We represent the $B_{\rm w}$ uncertainty due to density assignment uncertainty (σ_{ρ}) as the standard deviation of $B_{\rm w}$ estimates calculated using each density assignment method.

- 295 Interpolation uncertainty (σ_{INT})
- We represent the uncertainty due to interpolation/extrapolation of gridcell-averaged $b_{\rm w}$ in different ways for
- 297 LR and OK. LR interpolation uncertainty is represented by a multivariate normal distribution of possible
- regression coefficients (β_i) . The standard deviation of each distribution is calculated using the covariance of
- 299 β_i as outlined in Bagos and Adam (2015), which ensures that β_i are internally consistent. The β_i distributions
- are randomly sampled and used to calculate gridcell-estimated $b_{\rm w}$.
- 301 OK interpolation uncertainty is represented by the standard deviation for each gridcell-estimated value of
- $b_{\rm w}$ generated by the DiceKriging package. The standard deviation of $B_{\rm w}$ is then found by taking the square
- 303 root of the average variance of each gridcell-estimated $b_{\rm w}$. The final distribution of $B_{\rm w}$ values is centred at
- the $B_{\rm w}$ estimated with OK. For simplicity, the standard deviation of $B_{\rm w}$ values that result from either LR
- or OK interpolation/extrapolation uncertainty is referred to as $\sigma_{\rm INT}$.

RESULTS

306

307 Field measurements

- Snow depth
- 309 Mean snow depth varied systematically across the study region, with Glacier 4 having the highest mean
- 310 snow depth and Glacier 13 having the lowest (Fig. 2a). At each measurement location, the median range
- of measured depths (3–4 points) as a percent of the mean local depth is 2\%, 11\% and 12\%, for Glaciers 4,
- 2 and 13, respectively. While Glacier 4 has the lowest point-scale variability, as assessed above, it also has
- 313 the highest proportion of outliers, indicating a more variable snow depth across the glacier. The average
- standard deviation of all zigzag depth measurements is 0.07 m, 0.17 m and 0.14 m, for Glaciers 4, 2 and 13,
- respectively. When converted to values of $b_{\rm w}$ using the local FS-derived density measurement, the average
- standard deviation is 0.027 m w.e., 0.035 m w.e. and 0.040 m w.e. Winter-balance data for each zigzag are not
- 317 normally distributed (Fig. 3).
- $Snow \ density$
- Contrary to expectation, co-located FS and SP measurements are found to be uncorrelated ($R^2 = 0.25$,
- Fig. 2b). The FS appears to oversample in deep snow and undersample in shallow snow. Oversampling by
- 321 small-diameter sampling tubes has been observed in previous studies, with a percent error between 6.8%
- and 11.8% (e.g. Work and others, 1965; Fames and others, 1982; Conger and McClung, 2009). Studies that
- use FS often apply a 10% correction to all measurements for this reason (e.g. Molotch and others, 2005).

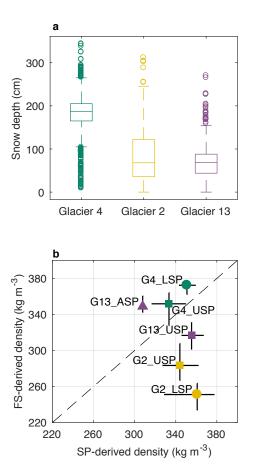

Fig. 2. Measured snow depth and density. (a) Boxplot of measured snow depth on Glaciers 4, 2 and 13 with the first quartiles (box), median (line within box), minimum and maximum values excluding outliers (bar) and outliers (circles), which are defined as being outside of the range of 1.5 times the quartiles (approximately $\pm 2.7\sigma$). (b) Comparison of depth-averaged densities estimated using Federal Sampler (FS) measurements and a wedge cutter in a snow pit (SP) for Glacier 4 (G4), Glacier 2 (G2) and Glacier 13 (G13). Labels indicate SP locations in the accumulation area (ASP), upper ablation area (USP) and lower ablation area (LSP). Error bars for SP-derived densities are calculated by varying the thickness and density of layers that are too hard to sample, and error bars for FS-derived densities are the standard deviation of measurements taken at one location. One-to-one line is dashed.

Oversampling has been attributed to slots "shaving" snow into the tube as it is rotated (e.g. Dixon and Boon, 2012) and to snow falling into the slots, particularly for snow samples with densities >400 kg m⁻³ and snow depths >1 m (e.g. Beaumont and Work, 1963). Undersampling is likely to occur due to loss of snow from the bottom of the sampler (Turcan and Loijens, 1975). Loss by this mechanism may have occurred in our study, given the isothermal and melt-affected snow conditions observed over the lower reaches of Glaciers 2 and 13. Relatively poor FS spring-scale sensitivity also calls into question the reliability of measurements for snow depths <20 cm.

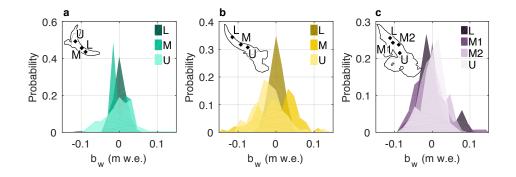

Fig. 3. Distributions of estimated winter-balance values for each zigzag survey in lower (L), middle (M) and upper (U) ablation areas (insets). Local mean has been subtracted. (a) Glacier 4. (b) Glacier 2. (c) Glacier 13.

Our FS-derived density values are positively correlated with snow depth ($R^2 = 0.59$). This relationship could be a result of physical processes, such as compaction in deep snow and preferential formation of depth hoar in shallow snow, but is more likely a result of measurement artefacts for a number of reasons. First, the total range of densities measured by the FS seems improbably large ($227-431 \,\mathrm{kg}\,\mathrm{m}^{-3}$). At the time of sampling the snow pack had little fresh snow, which confounds the low density values, and was not yet saturated and had few ice lenses, which confounds the high density values. Moreover, the range of FS-derived values is much larger than that of SP-derived values when co-located measurements are compared. Second, compaction effects of the magnitude required to explain the density differences between SP and FS measurements would not be expected at the measured snow depths (up to 340 cm). Third, no linear relationship exists between depth and SP-derived density ($R^2 = 0.05$). These findings suggest that the FS measurements have a bias for which we have not identified a suitable correction. Despite this bias, we use FS-derived densities to generate a range of possible b_w estimates and to provide a generous estimate of uncertainty arising from density assignment.

344 Density assignment

Given the lack of correlation between co-located SP- and FS-derived densities (Fig. 2), we use the densities derived from these two methods separately (Table 3). SP-derived regional (S1) and glacier-mean (S2) densities are within one standard deviation of the corresponding FS-derived densities (F1 and F2) although SP-derived density values are larger (see Supplementary Material, Table S3). For both SP- and FS-derived densities, the mean density for any given glacier (S2 or F2) is within one standard deviation of the mean across all glaciers (S1 or F1). Correlations between elevation and SP- and FS-derived densities are generally high (R² > 0.5) but vary between glaciers (Supplementary material, Table S3). For any given glacier, the standard deviation

Table 4. Glacier-wide winter balance ($B_{\rm w}$, m w.e.) estimated using linear regression and ordinary kriging for the three study glaciers. Root mean squared error (RMSE, m w.e.) is computed as the average of all RMSE values between gridcell-averaged values of $b_{\rm w}$ (the data) that were randomly selected and excluded from interpolation (1/3 of all data) and those estimated by interpolation. RMSE as a percent of the $B_{\rm w}$ is shown in brackets.

	Linea	r regression	Ordinary kriging			
	$B_{\rm w}$ RMSE		$B_{ m w}$	RMSE		
G 4	0.58	0.15~(26%)	0.62	0.11 (18%)		
G2	0.58	0.10 (17%)	0.35	0.06 (18%)		
G13	0.38	0.08 (21%)	0.27	0.06~(21%)		

of the 3–4 SP- or FS-derived densities is <13% of the mean of those values (S2 or F2) (Supplementary material, Table S3). We adopt S2 (glacier-wide mean of SP-derived densities) as the reference method of density assignment. Though the method described by S2 does not account for known basin-scale spatial variability in snow density (e.g. Wetlaufer and others, 2016), it is commonly used in winter balance studies (e.g. Elder and others, 1991; McGrath and others, 2015; Cullen and others, 2017).

357 Gridcell-averaged winter balance

The distributions of gridcell-averaged $b_{\rm w}$ values for the individual glaciers are similar to those in Fig. 2a but with fewer outliers (see Supplementary Material, Fig. S4). The standard deviations of $b_{\rm w}$ values determined from the zigzag surveys are almost twice as large as the mean standard deviation of point-scale $b_{\rm w}$ values within a gridcell measured along transects (see Supplementary Material, Fig. S5). However, a small number of gridcells sampled in transect surveys have standard deviations in $b_{\rm w}$ that exceed 0.25 m w.e. (~10 times greater than those for zigzag surveys).

364 Distributed winter balance

365 Linear regression

The highest values of estimated $b_{\rm w}$ are found in the upper portions of the accumulation areas of Glaciers 2 and 13 (Fig. 4). These areas also correspond to large values of elevation, slope, and wind redistribution. Extrapolation of the positive relation between $b_{\rm w}$ and elevation, as well as slope and Sx for Glacier 2, results in high $b_{\rm w}$ estimates and large relative uncertainty in these estimates (Fig. 5). On Glacier 4, the distributed $b_{\rm w}$ and the relative uncertainty are almost uniform (Fig. 4) due to the small regression coefficients for all topographic parameters. The explained variance of the LR-estimated $b_{\rm w}$ differs considerably between

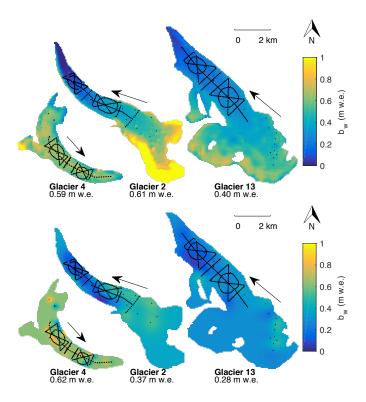

Fig. 4. Spatial distribution of winter balance $(b_{\rm w})$ estimated using linear regression (top row) and ordinary kriging (bottom row) with densities assigned as per S2 (Table 3). The linear regression method involves multiplying regression coefficients, found using cross validation and model averaging, by topographic parameters for each gridcell. Ordinary kriging uses the covariance of measured values to find a set of optimal weights for estimating values at unmeasured locations. Locations of snow-depth measurements taken in May 2016 are shown as black dots. Ice-flow directions are indicated by arrows. Values of $B_{\rm w}$ are given below labels.

glaciers (Fig. 6), with the best correlation between modelled- and observed- $b_{\rm w}$ occurring for Glacier 2. LR is an especially poor predictor of $b_{\rm w}$ on Glacier 4, where $B_{\rm w}$ can be estimated equally well using the mean of the data. RMSE is also highest for Glacier 4 (Table 4).

375 Ordinary kriging

For all three glaciers, large areas that correspond to locations far from measurements have $b_{\rm w}$ estimates equal to the kriging mean. Distributed $b_{\rm w}$ estimated with OK on Glacier 4 is mostly uniform except for local deviations close to measurement locations (Fig. 4) and relative uncertainty is highest close to measurement locations. Distributed $b_{\rm w}$ varies more smoothly on Glaciers 2 and 13 (Fig. 4). Glacier 2 has a distinct region of low estimated $b_{\rm w}$ (\sim 0.1 m w.e.) in the lower part of the ablation area, which corresponds to a wind-scoured region of the glacier. Glacier 13 has the lowest estimated mean $b_{\rm w}$ and only small deviations from this mean at measurement locations (Fig. 4). Relative uncertainty vary considerably across the three study glaciers with

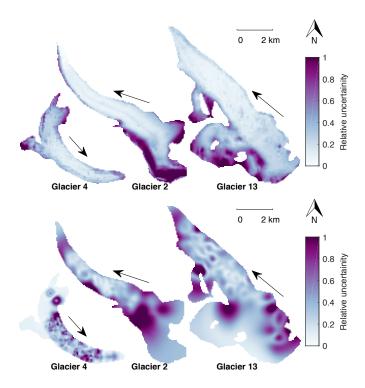

Fig. 5. Relative uncertainty in distributed winter balance $(b_{\rm w})$ (Fig. 4) found using linear regression (top row) and ordinary kriging (bottom row). Values closer to one indicate higher relative uncertainty. Ice-flow directions are indicated by arrows.

the greatest uncertainty just outside of the region with observed $b_{\rm w}$ (Fig. 5). As expected, explained variance of OK-estimated $b_{\rm w}$ is high for both Glaciers 2 and 13 (Fig. 6) because OK is a data-fitting algorithm. However, explained variance (Fig. 6) for Glacier 4 is relatively low and RMSE is relatively high (Table 4), indicating a highly variable distribution of $b_{\rm w}$.

Table 5. Standard deviation (×10⁻² m w.e.) of glacier-wide winter balance ($B_{\rm w}$) distributions arising from uncertainties in grid-scale $b_{\rm w}$ ($\sigma_{\rm GS}$), density assignment (σ_{ρ}), interpolation ($\sigma_{\rm INT}$) and all three sources combined ($\sigma_{\rm ALL}$) for linear regression (left columns) and ordinary kriging (right columns)

	Linear regression				Ordinary kriging			
	$\sigma_{ m GS}$	$\sigma_{ ho}$	σ_{INT}	σ_{ALL}	$\sigma_{ m GS}$	$\sigma_{ ho}$	σ_{INT}	σ_{ALL}
Glacier 4	0.86	1.90	2.13	2.90	0.17	2.16	14.35	14.62
Glacier 2	1.80	3.37	3.09	4.90	0.69	2.01	12.38	13.19
Glacier 13	1.12	1.68	2.80	3.20	0.56	1.29	9.75	10.48

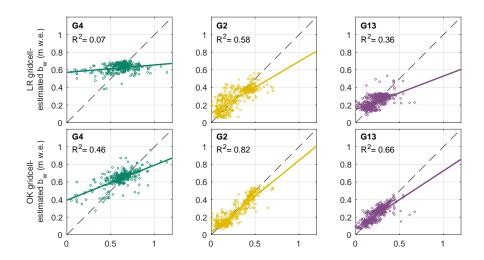

Fig. 6. Winter balance $(b_{\rm w})$ estimated by linear regression (LR, top row) or ordinary kriging (OK, bottom row) versus the grid-cell averaged $b_{\rm w}$ data for Glacier 4 (left), Glacier 2 (middle) and Glacier 13 (right). Each circle represents a single gridcell. Explained variance (\mathbb{R}^2) is provided. Best-fit (solid) and one-to-one (dashed) lines are shown.

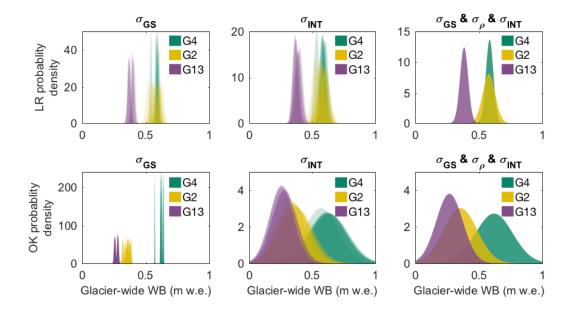

Fig. 7. Distributions of glacier-wide winter balance $(B_{\rm w})$ for Glaciers 4 (G4), 2 (G2) and 13 (G13) that arise from various sources of uncertainty. $B_{\rm w}$ distribution arising from grid-scale uncertainty $(\sigma_{\rm GS})$ (left column). $B_{\rm w}$ distribution arising from interpolation uncertainty (σ_{INT}) (middle column). $B_{\rm w}$ distribution arising from a combination of $\sigma_{\rm GS}$, $\sigma_{\rm INT}$ and density assignment uncertainty (σ_{ρ}) (right column). Results are shown for interpolation by linear regression (LR, top row) and ordinary kriging (OK, bottom row). Left two columns include eight distributions per glacier (colour) and each corresponds to a density assignment method (S1–S4 and F1–F4).

387 Uncertainty analysis using a Monte Carlo approach

Glacier-wide winter balance is affected by uncertainty introduced by the representativeness of gridcell-388 averaged values of $b_{\rm w}$ ($\sigma_{\rm GS}$), choosing a method of density assignment (σ_{ρ}), and interpolating/extrapolating 389 $b_{\rm w}$ values across the domain ($\sigma_{\rm INT}$). Using a Monte Carlo analysis, we find that interpolation uncertainty 390 contributes more to $B_{\rm w}$ uncertainty than grid-scale uncertainty or density assignment method. In other words, 391 the distribution of $B_{\rm w}$ that arises from grid-scale uncertainty and the differences in distributions between 392 methods of density assignment are smaller than the distribution that arises from interpolation uncertainty 393 (Fig. 7 and Table 5). The $B_{\rm w}$ distributions obtained using LR and OK overlap for a given glacier, but the 394 distribution modes differ (Fig. 7). OK-estimated values of $b_{\rm w}$ in the accumulation area are generally lower 395 (Fig. 4), which lowers the $B_{\rm w}$ estimate. The uncertainty in OK-estimated values of $B_{\rm w}$ is large, and unrealistic 396 $B_{\rm w}$ values of 0 m w.e. can be estimated (Fig. 7). 397 The values of $B_{\rm w}$ for our study glaciers (using LR and S2 density assignment method), with an uncertainty 398 equal to one standard deviation of the distribution found with Monte Carlo analysis, are: 0.59 ± 0.03 m w.e. 399 for Glacier 4, $0.61\pm0.05\,\mathrm{m}$ w.e. for Glacier 2 and $0.40\pm0.03\,\mathrm{m}$ w.e. for Glacier 13. The B_w uncertainty from 400 the three investigated sources of uncertainty ranges from 0.03 m w.e (5%) to 0.05 m w.e (8%) for LR estimates 401 and from 0.10 m w.e (37%) to 0.15 m w.e (24%) for ordinary-kriging estimates (Table 4). 402

403 DISCUSSION

404 Distributed winter balance

405 Linear regression

Of the topographic parameters in the LR, elevation (z) is the most significant predictor of gridcell-averaged 406 $b_{\rm w}$ for Glaciers 2 and 13, while wind redistribution (Sx) is the most significant predictor for Glacier 4 407 (Fig. 8). As expected, gridcell-averaged $b_{\rm w}$ is positively correlated with elevation where the correlation is 408 significant. It is possible that the elevation correlation was accentuated due to melt onset for Glacier 13 in 409 410 particular. Glacier 2 had little snow at the terminus likely due to steep ice and wind-scouring but the snow did not appear to have been affected by melt. Our results are consistent with many studies that have found 411 elevation to be the most significant predictor of seasonal snow accumulation data (e.g. Machguth and others, 412 2006; Grünewald and others, 2014; McGrath and others, 2015). The $b_{\rm w}$ -elevation gradient is $13\,{\rm mm}/100\,{\rm m}$ 413 on Glacier 2 and 7 mm/100 m on Glacier 13. These gradients are consistent with those reported for a few 414 glaciers in Svalbard (Winther and others, 1998) but are considerably smaller than many reported $b_{\rm w}$ -elevation 415

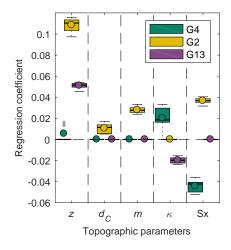

Fig. 8. Distribution of coefficients (β_i) determined by linear regression of gridcell-averaged b_w on DEM-derived topographic parameters for the eight different density assignment methods (Table 3). Coefficients are calculated using standardized data, so values can be compared across parameters. Regression coefficients that are not significant are assigned a value of zero. Topographic parameters include elevation (z), distance from centreline (d_C), slope (m), curvature (κ) and wind redistribution (Sx). Aspect (α) and "northness" (N) are not shown because coefficient values are zero in every case. The box plot shows first quartiles (box), median (line within box), mean (circle within box), minimum and maximum values excluding outliers (bars) and outliers (gray dots), which are defined as being outside of the range of 1.5 times the quartiles (approximately $\pm 2.7\sigma$).

gradients, which range between 60–240 mm/100 m (e.g. Hagen and Liestøl, 1990; Tveit and Killingtveit, 1994; 416 Winther and others, 1998). Extrapolating linear relationships to unmeasured locations typically results in 417 considerable estimation error, as seen by the large $b_{\rm w}$ values (Fig. 4) and large relative uncertainty (Fig. 5) 418 in the high-elevation regions of Glaciers 2 and 13. The low correlation between $b_{\rm w}$ and elevation on Glacier 419 4 is consistent with Grabiec and others (2011) and López-Moreno and others (2011), who conclude that 420 highly variable distributions of snow can be attributed to complex interactions between topography and the 421 422 atmosphere that cannot be easily quantified. The snow on Glacier 4 also did not appear to have been affected by melt and it is hypothesized that significant wind-redistribution processes, that were not captured by the 423 Sx parameter, covered ice-topography and produced a relatively uniform snow depth across the glacier. 424 Gridcell-averaged $b_{\rm w}$ is negatively correlated with Sx on Glacier 4, counter-intuitively indicating less snow 425 in what would be interpreted as sheltered areas. Gridcell-averaged $b_{\rm w}$ is positively correlated with Sx on 426

Glaciers 2 and 13. Our results corroborate those of McGrath and others (2015) in a study of six glaciers

427

in Alaska (DEM resolutions of 5 m) where elevation and Sx were the only significant parameters for all 428 glaciers; Sx regression coefficients were smaller than elevation regression coefficients, and in some cases, 429 negative. While our results point to wind having an impact on snow distribution, the wind redistribution 430 parameter (Sx) may not adequately capture these effects at our study sites. For example, Glacier 4 is 431 located in a curved valley with steep side walls, so specifying a single cardinal direction for wind may not be 432 433 adequate. Further, the scale of deposition may be smaller than the resolution of the Sx parameter estimated from the DEM. Creation of a parametrization for sublimation from blowing snow, which has been shown to 434 be an important mechanism of mass loss from ridges (e.g. Musselman and others, 2015), may also improve 435 explanatory power of LR for our study sites. 436 We find that transfer of LR coefficients between glaciers results in large estimation errors. Regression 437 coefficients from Glacier 4 produce the highest RMSE (0.38 m w.e. on Glacier 2 and 0.40 m w.e. on Glacier 438 13, see Table 4 for comparison) and $B_{\rm w}$ values are the same for all glaciers (0.64 m w.e.) due to the dominance 439 of the regression intercept. Even if the LR is performed with $b_{\rm w}$ values from all glaciers combined, the resulting 440 coefficients produce large RMSE when applied to individual glaciers (0.31 m w.e., 0.15 m w.e. and 0.14 m w.e. 441 for Glaciers 4, 2 and 13, respectively). Our results are consistent with those of Grünewald and others (2013), 442 who found that local statistical models cannot be transferred across basins and that regional-scale models 443

445 Ordinary kriging

444

Due to a paucity of data, simple kriging produces almost uniform gridcell-estimated $b_{\rm w}$ in the accumulation area of each glacier, inconsistent with observations described in the literature (e.g. Machguth and others, 2006; Grabiec and others, 2011). Glacier 4 has the highest estimated mean with large deviations from the mean at measurement locations. The longer correlation lengths of the data for Glaciers 2 and 13 result in a more smoothly varying distributed $b_{\rm w}$. As expected, extrapolation using OK leads to large uncertainty (Fig. 5), further emphasizing the need for spatially distributed point-scale measurements.

are not able to explain the majority of observed variance in winter balance.

452 LR and OK comparison

LR and OK produce similar estimates of distributed $b_{\rm w}$ (Fig. 5) and $B_{\rm w}$ (\sim 0.60 m w.e., Table 4) for Glacier 454 4 but both are relatively poor predictors of $b_{\rm w}$ in measured gridcells (Fig. 6). For Glaciers 2 and 13, OK estimates are more than \sim 0.22 m w.e. (39%) and \sim 0.11 m w.e. (30%) lower than LR estimates, respectively (Table 4). RMSE as a percentage of the $B_{\rm w}$ is lower for OK than LR only for Glacier 4 but the absolute RMSE of OK is \sim 0.03 m w.e. lower for all glaciers, likely because OK is a data-fitting interpolation method

(Table 4). Gridcell-estimated values of $b_{\rm w}$ found using LR and OK differ markedly in the upper accumulation 458 areas of Glaciers 2 and 13, where observations are sparse and topographic parameters, such as elevation, 459 vary considerably. The influence of elevation results in substantially higher LR-estimated values of $b_{\rm w}$ at 460 high elevation, whereas OK-estimated values are more uniform. Estimates of ablation-area-wide $B_{\rm w}$ differ 461 by <6% between LR and OK on each glacier, further emphasizing the combined influence of interpolation 462 463 method and measurement scarcity in the accumulation area on $B_{\rm w}$ estimates.

Uncertainty analysis using a Monte Carlo approach

464

465

Interpolation/extrapolation of $b_{\rm w}$ data is the largest contributor of $B_{\rm w}$ uncertainty in our study. These results caution strongly against including values of $B_{\rm w}$ in comparisons with remote sensing- or model-derived 466 estimates of $B_{\rm w}$. If possible, such comparisons should be restricted to point-scale data. Grid-scale uncertainty 467 $(\sigma_{\rm GS})$ is the smallest assessed contributor to overall $B_{
m w}$ uncertainty. This result is consistent with the generally 468 smoothly-varying snow depths encountered in zigzag surveys, and previously reported ice-roughness lengths 469 on the order of centimetres (e.g. Hock, 2005) compared to snow depths on the order of decimetres to metres. 470 Given our assumption that zigzags are an adequate representation of grid-scale variability, the low $B_{\rm w}$ 471 uncertainty arising from σ_{GS} implies that subgrid-scale sampling need not be a high priority for reducing 472 overall uncertainty. Our assumption that the 3-4 zigzag surveys can be used to estimate glacier-wide $\sigma_{\rm GS}$ 473 may be flawed, particularly in areas with debris cover, crevasses and steep slopes. 474 Our analysis did not include uncertainty arising from density measurement errors associated with the FS, 475

wedge cutters and spring scales, from vertical and horizontal errors in the DEM or from error associated with 476 estimating measurement locations based on the GPS position of the lead observer. We assume that these 477 sources of uncertainty are either encompassed by the sources investigated or are negligible. 478

Regional winter-balance gradient 479

Although we find considerable inter- and intra-basin variability in winter balance, our results are consistent 480 with a regional-scale winter-balance gradient for the continental side of the St. Elias Mountains (Fig. 9). 481 482 Winter-balance data are compiled from Taylor-Barge (1969), the three glaciers presented in this paper and two SP we analyzed near the head of the Kaskawulsh Glacier between 20–21 May 2016. The data show a linear 483 decrease of $0.024\,\mathrm{m\,w.e.~km^{-1}}$ ($\mathrm{R}^2=0.85$) in winter balance with distance from the regional topographic 484 divide between the Kaskawulsh and Hubbard Glaciers, as identified by Taylor-Barge (1969). While the three 485 study glaciers fit the regional trend, the same relationship would not apply if just the Donjek Range were 486 considered. We hypothesize that interaction between meso-scale weather patterns and large-scale mountain 487

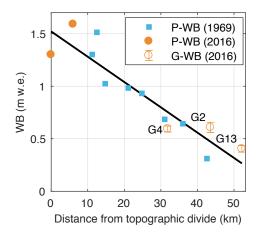

Fig. 9. Relationship between winter balance and linear distance from the regional topographic divide between the Kaskawulsh and Hubbard Glaciers in the St. Elias Mountains. Point-scale values of winter balance from snow-pit data reported by Taylor-Barge (1969) (blue boxes, P-WB). LR-estimated glacier-wide winter balance ($B_{\rm w}$) calculated using density assignment S2 for Glaciers 4 (G4), 2 (G2) and 13 (G13) with errors bars calculated as the standard deviation of Monte Carlo-derived $B_{\rm w}$ distributions (this study) (open orange circles, G-WB). Point-scale winter balance estimated from snow-pit data at two locations in the accumulation area of the Kaskawulsh Glacier, collected in May 2016 (unpublished data, SFU Glaciology Group) (filled orange dots, P-WB). Black line indicates best fit ($R^2 = 0.85$).

topography is a major driver of regional-scale winter balance. Further insight into regional-scale patterns of winter balance in the St. Elias Mountains could be gained by investigating moisture source trajectories and the contribution of orographic precipitation.

491 Limitations and future work

The potential limitations of our work include the restriction of our data to a single year, minimal sampling in the accumulation area, the problem of uncorrelated SP- and FS-derived densities, a sampling design that could not be optimized *a priori*, the assumption of spatially uniform subgrid variability and lack of more finely resolved DEMs.

Inter-annual variability in winter balance is not considered in our study. A number of studies have found temporal stability in spatial patterns of snow distribution and that statistical models based on topographic parameters could be applied reliably between years (e.g. Grünewald and others, 2013). For example, Walmsley (2015) analyzed more than 40 years of winter balance recorded on two Norwegian glaciers and found that snow distribution is spatially heterogeneous yet exhibits robust temporal stability. Contrary to this, Crochet and others (2007) found that snow distribution in Iceland differed considerably between years and depended 505

506

507

508

509

510

primarily on the dominant wind direction over the course of a winter. Therefore, multiple years of snow depth and density measurements, that are not necessarily consecutive, are needed to better understand inter-annual variability of winter balance within the Donjek Range.

There is a conspicuous lack of data in the accumulation areas of our study glaciers. With increased sampling in the accumulation area, interpolation uncertainties would be reduced where they are currently greatest and the LR would be better constrained. Although certain regions of the glaciers remain inaccessible for direct measurements, other methods of obtaining winter-balance measurements, including ground-penetrating radar and DEM differencing with photogrammetry or lidar, could be used in conjunction with manual probing to increase the spatial coverage of measurements.

The lack of correlation between SP- and FS-derived densities needs to be reconciled. Contrary to our results, most studies that compare SP- and FS-derived densities report minimal discrepancy (e.g. Dixon and Boon, 2012, and sources within). Additional co-located density measurements are needed to better compare the two methods of obtaining density values. Comparison with other FS would also be informative. Even with this limitation, density assignment was, fortunately, not the largest source of uncertainty in estimating glacier-wide winter balance.

Our sampling design was chosen to achieve broad spatial coverage of the ablation area, but is likely too finely resolved along transects for many mass-balance surveys to replicate. An optimal sampling design would minimize uncertainty in winter balance while reducing the number of required measurements. Analysis of the estimated winter balance obtained using subsets of the data is underway to make recommendations on optimal transect configuration and along-track spacing of measurements. López-Moreno and others (2010) found that 200–400 observations are needed within a non-glacierized alpine basin (6 km²) to obtain accurate and robust snow distribution models. Similar guidelines would be useful for glacierized environments.

In this study, we assume that the subgrid variability of winter balance is uniform across a given glacier.

Contrary to this assumption, McGrath and others (2015) found greater variability of winter-balance values

close to the terminus. Testing our assumption could be a simple matter of prioritizing the labour-intensive

zigzags surveys. To ensure consistent quantification of subgrid variability, zigzag survey measurements could

also be tested against other measurements methods, such as lidar.

DEM gridcell size is known to influence values of computed topographic parameters (Zhang and Montgomery, 1994; Garbrecht and Martz, 1994; Guo-an and others, 2001; López-Moreno and others, 2010). The relationship between topographic parameters and winter balance is, therefore, not independent of DEM

gridcell size. For example, Kienzle (2004) and López-Moreno and others (2010) found that a decrease in 532 spatial resolution of the DEM results in a decrease in the importance of curvature and an increase in the 533 importance of elevation in LR of snow distribution on topographic parameters in non-glacierized basins. The 534 importance of curvature in our study is affected by the DEM smoothing that we applied to obtain a spatially 535 continuous curvature field (see Supplementary Material, Fig. S1). A comparison of regression coefficients 536 537 from high-resolution DEMs obtained from various sources and sampled with various gridcell sizes could be used to characterize the dependence of topographic parameters on DEMs, and therefore assess the robustness 538 of inferred relationships between winter balance and topographic parameters. 539

CONCLUSION

558

559

560

540 We estimate winter balance for three glaciers (termed Glacier 2, Glacier 4 and Glacier 13) in the St. Elias 541 Mountains, Yukon, Canada from multiscale snow depth and density measurements. Linear regression and 542 ordinary kriging are used to obtain estimates of distributed winter balance (b_w) . We use Monte Carlo analysis 543 to evaluate the contributions of interpolation, assignment of snow density and grid-scale variability of winter 544 balance to uncertainty in estimates of glacier-wide winter balance $(B_{\rm w})$. 545 Values of $B_{\rm w}$ estimated using linear regression and ordinary kriging differ by up to 0.24 m w.e. (\sim 50%). We 546 find that interpolation uncertainty is the largest assessed source of uncertainty in $B_{\rm w}$ (7% for linear-regression 547 548 estimates and 34% for ordinary-kriging estimates). Uncertainty resulting from the method of density assignment is comparatively low, despite the wide range of methods explored. Given our representation of 549 grid-scale variability, the resulting $B_{\rm w}$ uncertainty is small indicating that extensive subgrid-scale sampling 550 is not required to reduce overall uncertainty. 551 Our results suggest that processes governing distributed $b_{\rm w}$ differ between glaciers, highlighting the 552 importance of regional-scale winter-balance studies. The estimated distribution of b_w on Glacier 4 is 553 characterized by high variability, as indicated by the poor correlation between estimated and observed values 554 555 and large number of data outliers. Glaciers 2 and 13 appear to have lower spatial variability, with elevation being the dominant predictor of gridcell-averaged $b_{\rm w}$. A wind-redistribution parameter is found to be a weak 556 but significant predictor of $b_{\rm w}$, though conflicting relationships between glaciers make it difficult to interpret. 557

The major limitations of our work include the restriction of our data to a single year and minimal sampling in

the accumulation area. Although challenges persist when estimating winter balance, our data are consistent

with a regional-scale winter-balance gradient for the continental side of the St. Elias Mountains.

561 AUTHOR CONTRIBUTION STATEMENT

- 562 AP planned and executed the data collection, performed all calculations and drafted the manuscript. GF
- 563 conceived of the study, contributed to field planning and data collection, oversaw all stages of the work and
- edited the manuscript. VR provided guidance with statistical methods and edited the manuscript.

565 ACKNOWLEDGEMENTS

- 566 We thank the Kluane First Nation (KFN), Parks Canada and the Yukon Territorial Government for granting
- 567 us permission to work in KFN Traditional Territory and Kluane National Park and Reserve. We are
- 568 grateful for financial support provided by the Natural Sciences and Engineering Research Council of Canada,
- 569 Simon Fraser University and the Northern Scientific Training Program. We kindly acknowledge Kluane Lake
- 570 Research Station, Sian Williams, Lance Goodwin and Trans North pilot Dion Parker for facilitating field
- 571 logistics. We are grateful to Alison Criscitiello and Coline Ariagno for all aspects of field assistance and Sarah
- 572 Furney for assistance with data entry. Thank you to Etienne Berthier for providing us with the SPIRIT SPOT-
- 573 5 DEM and for assistance in DEM correction. We are grateful to Derek Bingham and Michael Grosskopf for
- assistance with the statistics, including ordinary kriging. Luke Wonneck, Leif Anderson and Jeff Crompton
- 575 all provided thoughtful and constructive comments on drafts of the manuscript.
